Abstract

Dermal drug administration can be a preferred route for the delivery of drugs for local or systemic action, with numerous advantages over oral administration. Physiologically Based Pharmacokinetic (PBPK) models have recently gained significant attention in regulatory submissions to quantitatively predict drug-drug interactions (DDIs) and absorption/bioavailability processes [1, 2]. A PBPK approach has a strong potential to help bridge the gap in clinical knowledge in a situation where clinical studies are either difficult or practically infeasible.

Main objective of the current project was to develop and assess a PBPK model for buprenorphine (BUP) and its metabolite norbuprenorohine (NOR) dermal patches using available physico-chemical, in vitro ADME and formulation specific data for prediction of systemic exposure.

Methods

Prior ADME and formulation specific in vitro data of buprenorphine and its main metabolite norbuprenorohine were collated from publicly available sources. This includes the enzyme specific metabolism information (intrinsic clearances for CYP3A4, CYP2B6, and UGT1A1). The data were used in the Simcyp Simulator (V16) to develop the parent and metabolite compound files. The parent-metabolite model was qualified against published clinical studies using intravenous (bolus and infusion) administration of buprenorphine and the observed plasma concentration of buprenorphine and when available norbuprenorohine. After addition of the formulation (in vitro release rate from the patch, dose, thickness) and application (location and area) specific data the qualified compound files were used to predict the plasma exposure after single and multiple dermal patch application using the Multi-Phase Multi-Layer (MPML) Mechanistic Dermal absorption model implemented within the Simcyp Simulator (Figure 1).

Two IV clinical studies were used to validate the developed compound files [1,2]. Norbuprenorohine clearance was assumed to be equal to buprenorphine.

Figure 1. BUP and NOR predicted plasma exposure after IV dose (bolus and infusion).

For topical administration of buprenorphine, visual checks indicated that the model adequately predicted the buprenorphine and norbuprenorohine concentrations (Figure 2A and 2B – Kapil 2012 [3] and Kapil 2013 [4] study respectively).

Conclusions

Verified PBPK models can be used for virtual assessment of various clinical scenarios including long-term use or misuse and overdose. The ability to simulate and analyse individual profiles for different populations makes such models potentially useful for assessing exposure and safety aspects of dermal formulations, in particular, the in silico based cardiac safety assessment.

Acknowledgement

Funding for the work presented here was made possible, in part, by the Food and Drug Administration through grant 1U01FD005225-01. The Simcyp Simulator is freely available, following completion of the training workshop, to approved members of academic institutions and non-for-profit organizations for research and teaching purposes.
